Final Project: Description Using Models

UCB MIDS 203 Fall 2026 Section 6 Final Project Report

Vlad Lee, Sophia Liang, Mark Randall

1. Introduction

Our research question is to describe at a country level how the Life Expectancy is related to economic development, measured by GDP per capita. Our audience is individuals who are not socio-economic professionals, but would like to expand their worldview of how a range of societal metrics can influence the typical individual's life expectancy, and understand broader patterns in global development and living standards. The larger context of the question lies in discussions of economic development, global inequality, and public health, where researchers and policymakers aim to understand why countries experience different health outcomes and living standards.

Predicting life expectancy is studied by Samuel Preston(1975), who proposed a Preston curve, which demonstrates a concave relationship between life expectancy and GDP per capita. Additionally, Roffia et al. conducted a longitudinal study to determine life expectancy at birth based on certain socioeconomic and demographic factors. Our rerport brings together multiple dimensions of national development in one accessible country-level framework, providing a holistic picture describing how multiple kinds of determinants interact and influence life expectancy.

2. Source Data

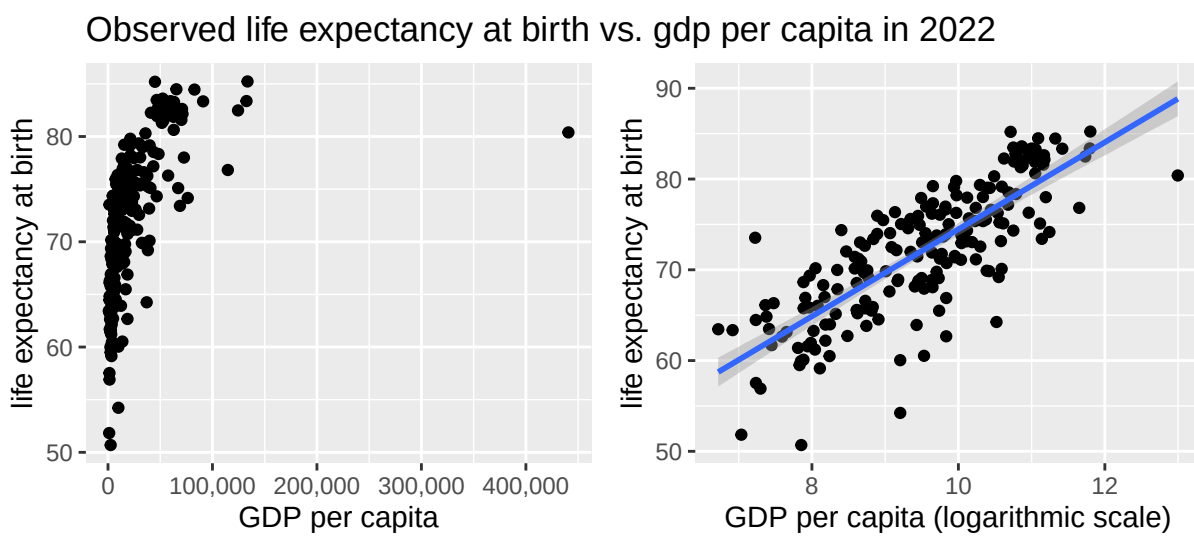
Our data is sourced from Gapminder, a Swedish organization that curates reliable data on global trends, compiled from sources such as the World Bank. The data includes annual country level observations spanning multiple decades. We construct a cross sectional dataset using data from 2022, resulting in one row per country (193 observations). We use country metrics as our features that are normalized (e.g. per person) to remove population size effects.

Each country is represented by a 3-letter country code and country long name. The outcome variable for our analysis is life expectancy (**lex**), which captures overall population health. Our primary explanatory variable is GDP per capita (**gdp_pcap**), which measures economic development. Though the online dataset includes hundreds of indicators, we have selected subset to represent broad categories of health, inequality, population demographics, economy and infrastructure:

children_per_woman_total_fertility	average_daily_income
population_density_per_square_k	gini coefficient
cell_phones_per_100_people	median_age_years
broadband_subscribers_per_100_p	co2_pcap_cons

3. Primary Analysis

Our primary anlysis describes the relationship between life expectancy at birth and GDP per capita across our country data for 2022. GDP per capita is a currency measurement and currency data (e.g. salary, earnings) is typically well suited to a logarithmic transformation. We plot the observed life expectancy data against the observed GDP per capita data, and note that a logarithmic transformation does capture a linear relationship more effectively than the untransformed data:



The correlation coefficient of life expectancy against the log of GPD per capita is 0.796, supporting the clear linear relationship indicated visually in the scatter plot. We regress life expectancy at birth on GRP per capita and following the application of OLS we specify as model as:

$$\text{lex} = 26.501 + 4.796 \cdot \log(\text{GDP per capita})$$

The observed vs. fitted plot suggests that log-GDP-pcap model captures the general positive correlation with life expectancy, since fitted values track the observed values well. However, the residuals vs. fitted values plot shows a slight systematic curvature rather than a random scatter around zero. This demonstrates that GDP per capital does not capture the relationship completely and additional predictors are necessary to improve the model fit.

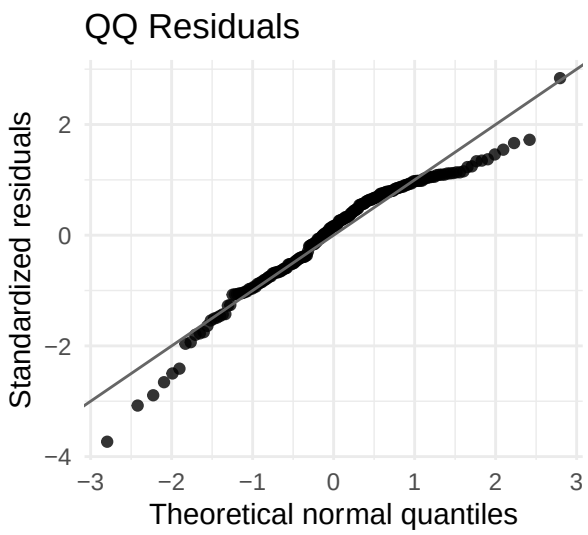
We perform a t-test of the simple model coefficients using robust variance. In this model and all subsequent specifications, we report robust standard errors to account for heteroskedasticity:

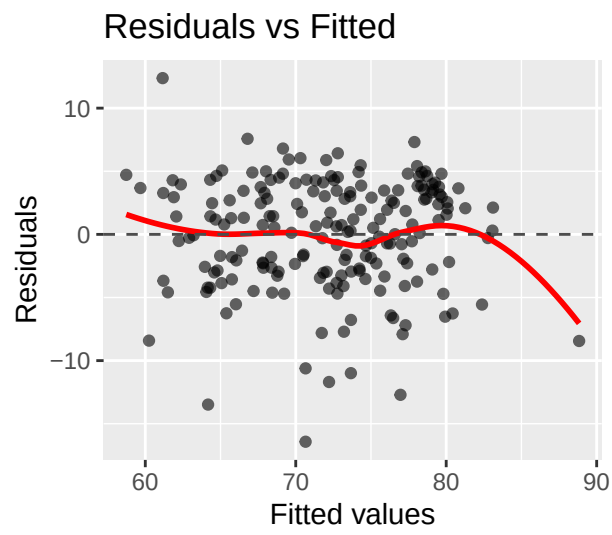
```
##
## t test of coefficients:
##
##               Estimate Std. Error t value  Pr(>|t|)
## (Intercept)   26.50065    2.70927  9.7815 < 2.2e-16 ***
## log(gdp_pcap)  4.79633    0.27998 17.1311 < 2.2e-16 ***
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
```

The p-value is below 0.001 and much smaller than our target level of significance at 0.05. As a result, we can reject our NULL hypothesis and conclude that there is overwhelming evidence that there is a postive relationship between GDP per capita and life expectancy. A 10 percent increase in GDP per capita is associated with an approximately 0.48 year increase in life expectancy, though this reflects a cross country relationship rather than a causal effect within a given country.

4. CLM Assumptions

In order to visually assess the five assumptions inherent in the classical linear regression model, we generate the following plots:





1. **IID**: Country data will never be perfectly independent due to similarities in culture, geography, and history, but we do not observe any clear patterns in the residuals that would suggest strong dependence.
2. **Linear conditional expectation**: The residuals vs. fitted values plot shows a slight systematic curvature rather than a random scatter around zero, with one extreme outlier.
3. **Perfect colineaerity**: Our primary model has a single feature and thus does not violate the perfect collinearity assumption. In our expanded model, we exclude average daily income due to its high correlation with GDP per capita, which would have introduced multicollinearity.
4. **Homoskedasticity**: The Breusch-Pagan test yields a p-value of 0.505, which is well above a target level 0.05. As such, we cannot reject the null hypothesis of homoskedasticity.
5. **Normality of errors**: The QQ plot of the standardized residuals shows that the residuals are approximately normally distributed, with points roughly following the theoretical line. There is however deviation in the tails, which may be due to the presence of outliers or the small sample size. Overall, the normality assumption appears to be reasonably satisfied.

5. Expanded Analysis

To better understand the relationship between life expectancy and broader measures of development, we extend our baseline model by incorporating additional variables capturing demographics, inequality, and population characteristics. Before constructing the expanded model, we note that several variables are strongly correlated with GDP per capita. In particular, average daily income is highly correlated with GDP per capita (correlation ≈ 0.96), indicating that both variables capture similar aspects of economic development. Including both in the model would introduce multicollinearity and lead to unstable coefficient estimates. For this reason, we exclude average daily income and retain GDP per capita as our primary measure of economic development.

5.1 Demographic Factors

We first extend the model by adding demographic features for fertility (children per woman) and median age. Higher fertility is associated with lower life expectancy and higher median age is associated with higher life expectancy.

$$\begin{aligned} \text{lex} = 46.327 &+ 2.415 \cdot \log(\text{GDP per capita}) \\ &- 1.274 \cdot \text{children per woman} \\ &+ 0.205 \cdot \text{median age} \end{aligned}$$

We observe that the median age of the current population is highly correlated with life expectancy at birth (0.79), an may introduce collinearity concerns. A coefficient test on this specification does show that all three coefficients are statistically significant at the 0.05 level, with robust standard errors. Including these variables improves model fit and reduces the magnitude of the GDP coefficient, suggesting that part of the relationship between income and life expectancy operates through demographic factors. An ANOVA test confirms that adding the demographic factors significantly improves model fit ($F = 18.85$, $p < 0.0001$), indicating that these factors add meaningful explanatory power for life expectancy.

5.2 Inequality

We next incorporate inequality by adding the Gini index, a measure of wealth inequality. We observe a negative and statistically significant coefficient for the Gini index, indicating that higher inequality is associated with lower life expectancy, holding other factors constant. We now omit median age since it becomes statistically insignificant in this specification ($p = 0.07$) but highly collinear with life expectancy (VIF=5.4), while the effects of GDP per capita and fertility remain statistically significant and consistent in direction.

$$\begin{aligned} \text{lex} = 59.131 &+ 2.660 \cdot \log(\text{GDP per capita}) \\ &- 2.061 \cdot \text{children per woman} \\ &- 0.179 \cdot \text{Gini} \end{aligned}$$

An ANOVA test comparing models with and without inequality shows that adding the Gini index significantly improves model fit ($F = 15.15$, $p = 0.0001$). We conclude that including inequality explains significantly more variation in life expectancy.

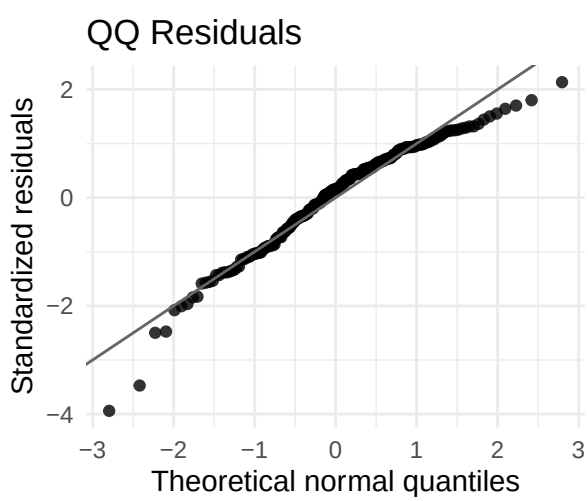
Appendix

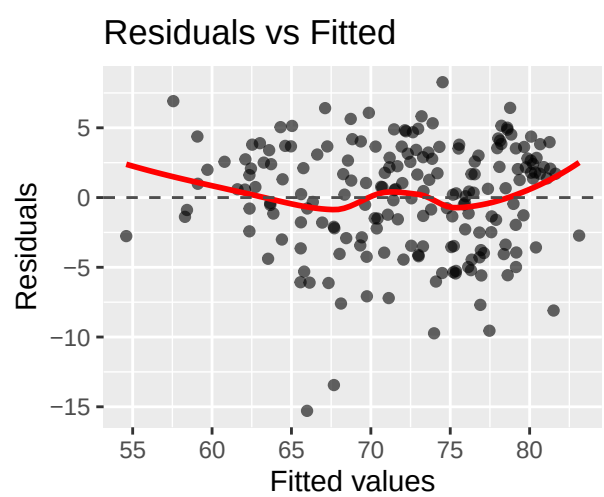
Datasource

Our data was initially sourced from www.gapminder.org, using the interface provided on the website. After confirmning our approach, we downloaded individual CSV files for each indicator from https://github.com/open-numbers/ddf–open_numbers–world_development_indicators and combined these into one dataset. The code for this wrangling process is in the data_cleaning folder in our project repo. We removed two countries without life expectancy data. **Given the overall clean dataset is small, we have included this CSV file in our repo under data/combined_data_2022.csv and recommend that the instructor access this file directly to assess the analysis presented herein.**

Model Specifications

Our question examines the relationship between GDP per capita and life expectancy. Initial visual analysis led us to apply a logarithmic transformation to GDP per capita. When considering an expanded version of the model, we first did a bivarite anlaysis of each variable with life expectancy (scatter plot, correlation coefficient and linear regression with coefficient test). We also considered the correlation of each variable with GDP per capita to identify potential multicollinearity concerns and excluded average daily income as a result.

We constructed our model in a stepwise fashion, starting with demographic factors (fertility and median age), and then proceeding to add the gini coefficient to capture inequality. Finally, we removed the median age variable since it becomes statistically insignificant in the presence of the gini coefficient, and is highly collinear with life expectancy. Analysis confirms that the remaining five variables are not statistically signficiant predictors and we exclude them from our final model specification to avoid overfitting.




The final residuals vs. fitted values plot parabolic curvature rather than a straight line, impying the addition of an x^2 term may improve model fit. However, we find that adding a squared term for fertility does not signficiantly improive model fit. The curvature may rather be driven by outliers, but we do not have a strong theoretical reason to exclude them from our analysis.
